Gaurav Pandey  
Research Scientist, IBM Research

# Regularized reward maximization

- Maximize the reward
- Minimize the KL divergence
- Add a scaling factor  $\beta$  & combine

# The regularized reward maximization objective

# Regularized reward

$$E_{\pi_\theta(y|x)} \left[ r(x,y) - \beta \log \frac{\pi_\theta(y|x)}{\pi_{ref}(y|x)} \right] \equiv E_{\pi_\theta(y|x)} r_s(x,y)$$

where  $r_s(x,y) = r(x,y) - \beta \log \frac{\pi_\theta(y|x)}{\pi_{ref}(y|x)}$

- $r_s(x,y)$  is the regularized reward
- Maximizing the regularized reward ensures
  - High reward outputs as decided by the reward model
  - Outputs that have reasonable probability under the reference model

# How to maximize – The REINFORCE algorithm?

- Compute the gradient of the objective.
- Train using Adam/Adagrad optimization algorithms

$$\nabla_{\theta} E_{\pi_{\theta}}(y|x) r_s(x, y)$$

# Computing the derivative

$$\sum_{y \in Y} \nabla_{\theta} \pi_{\theta}(y|x) r_s(x, y)$$

- Exact computation of the gradient is intractable
  - Output space is too large
- Can we approximate it using samples?
- To be able to do that, we need an expression of the form

$$E_{\pi_{\theta}}(y|x)[...] = \sum_{y \in Y} \pi_{\theta}(y|x) [...]$$

- How to transform the derivative to this desired form?

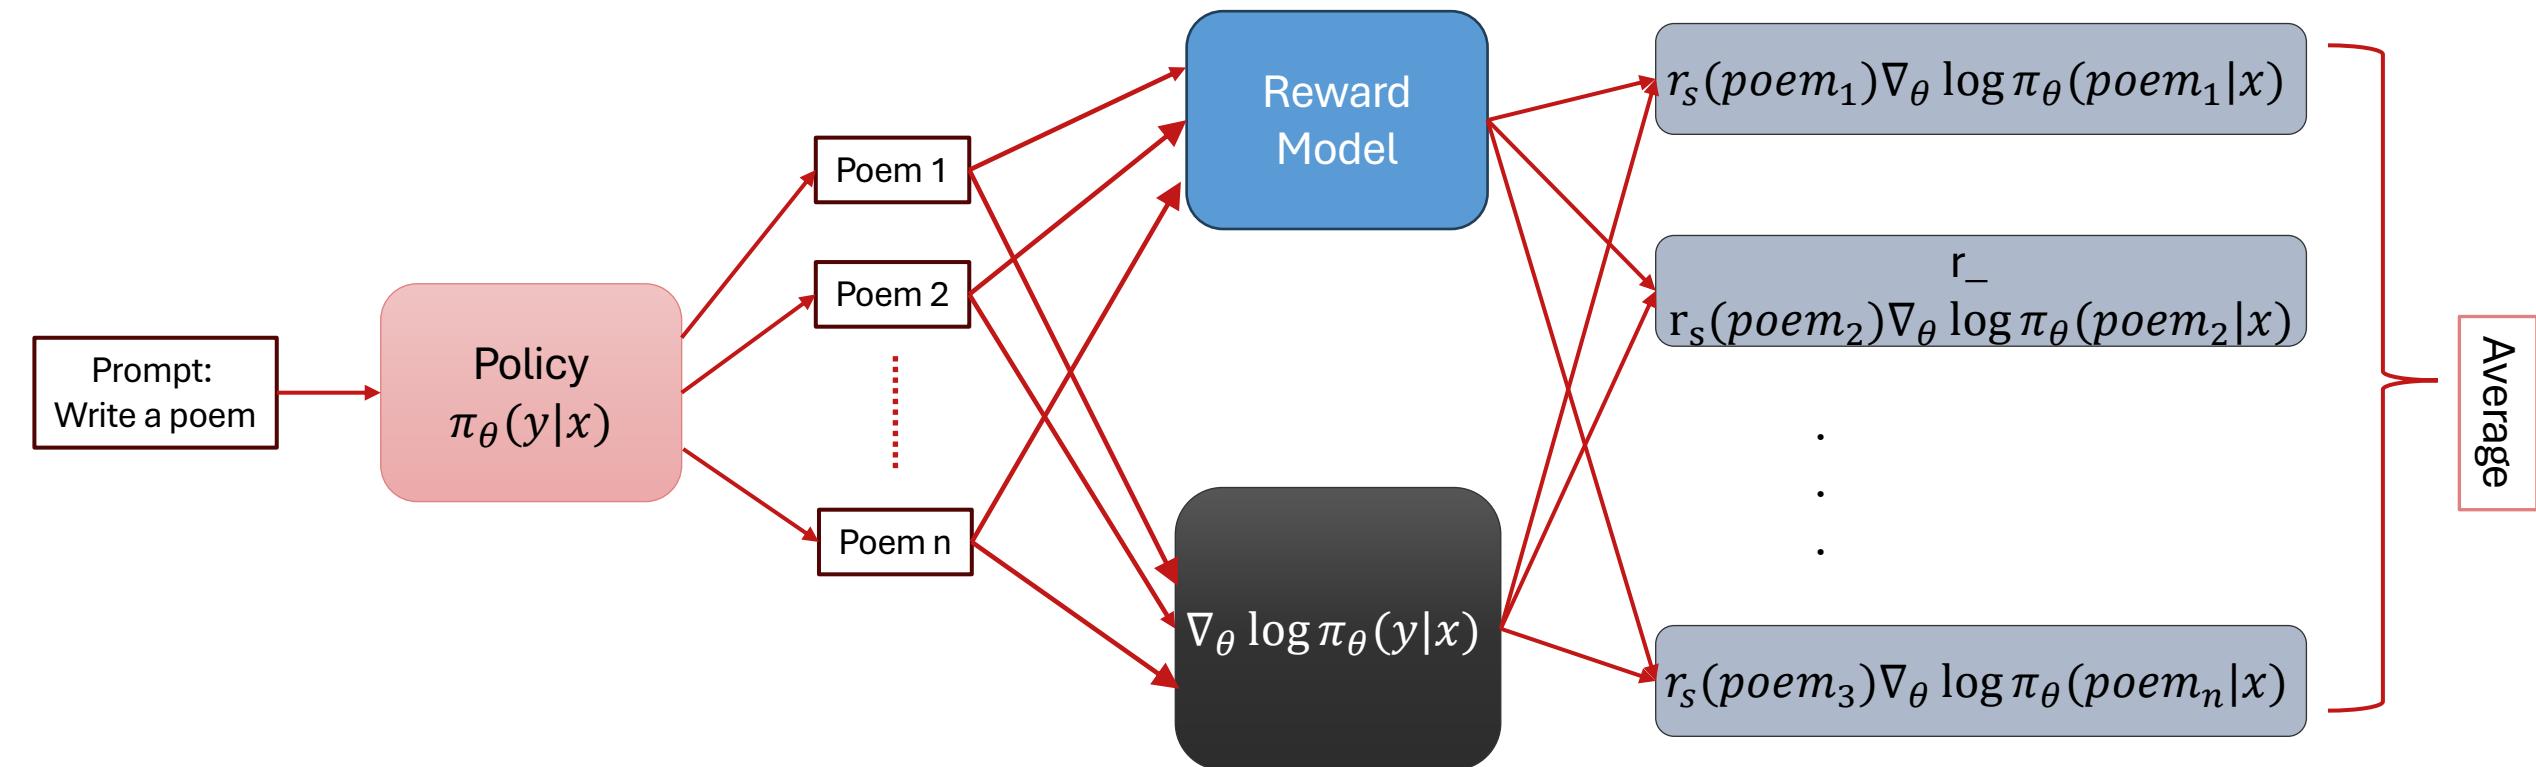

# The log-derivative trick

$$\nabla_{\theta} \log \pi_{\theta}(y|x) =$$

Replacing it in the derivative, we get

# Monte Carlo approximation

# Expanding the gradient

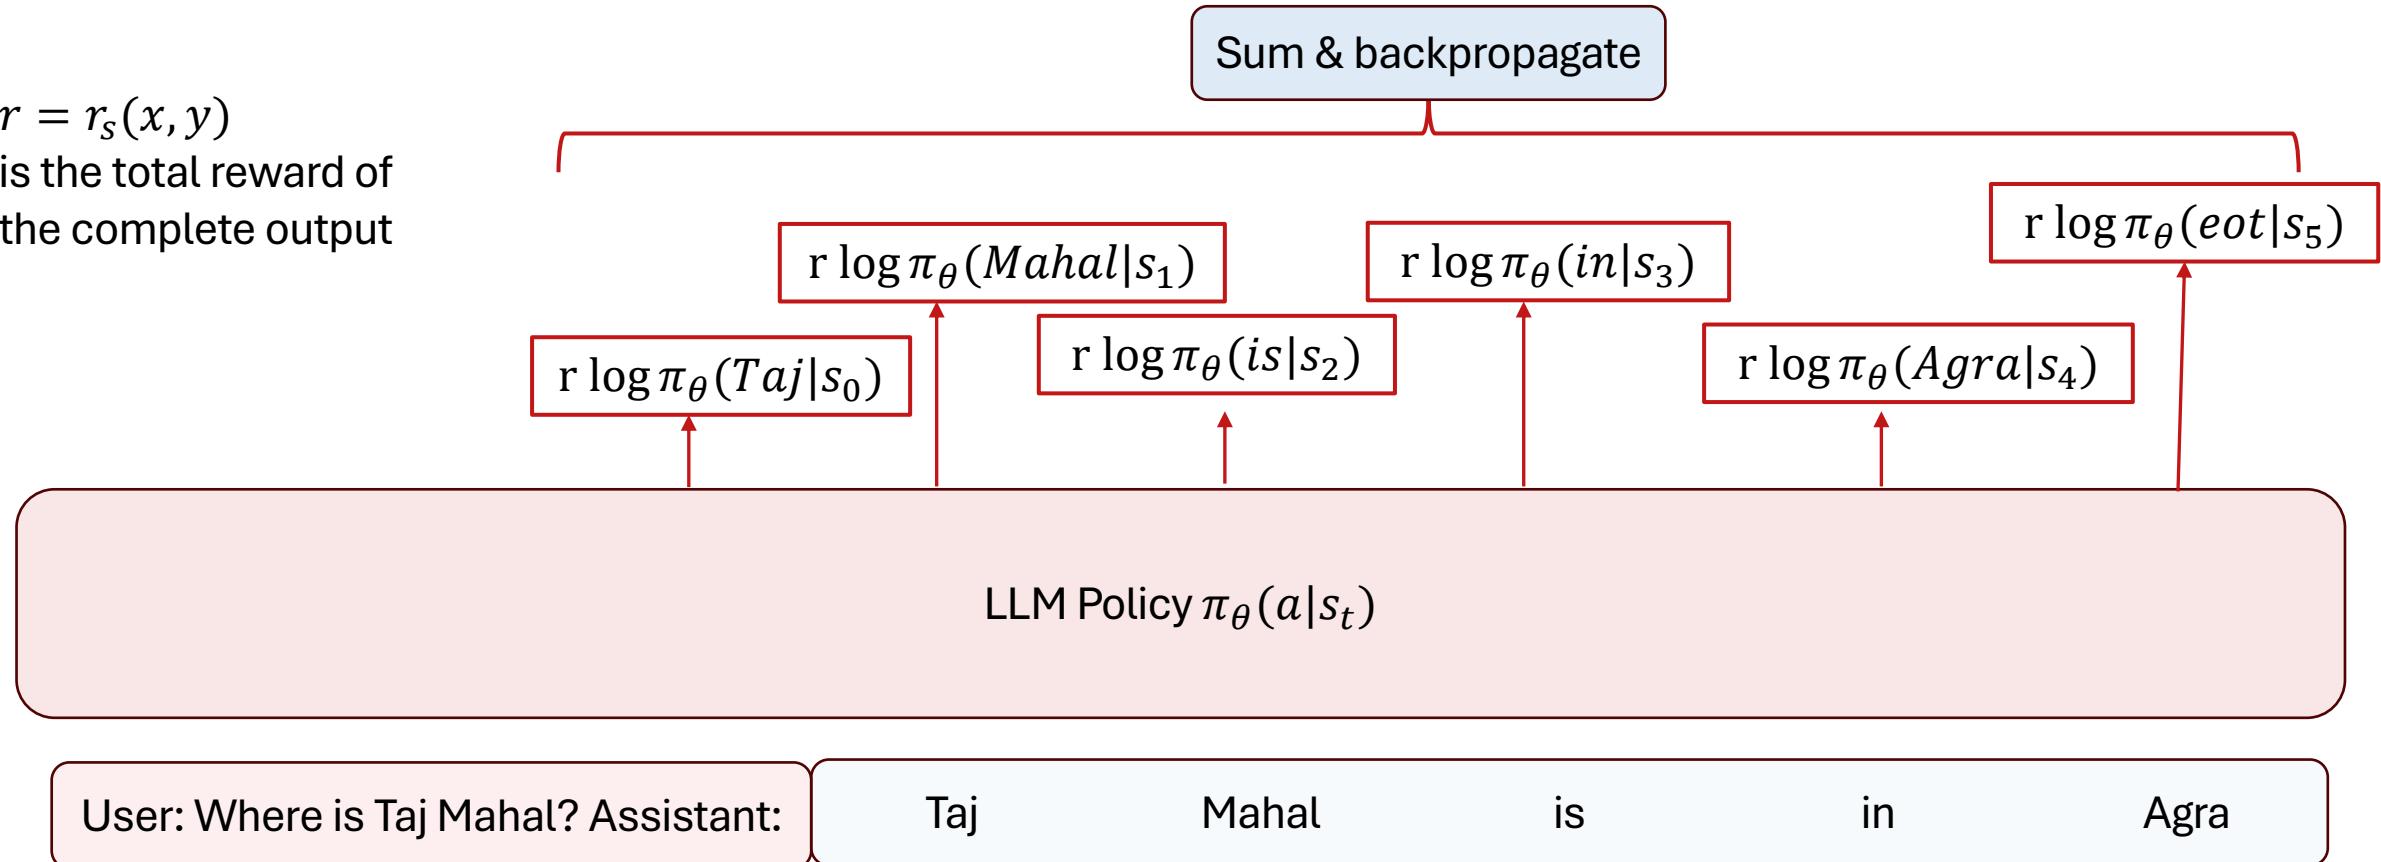

- Let  $y = (a_1, \dots, a_m)$  be the tokens of  $y$ .
- $r_s(x, y) \nabla_{\theta} \log \pi_{\theta}(y|x) =$

# Implementing REINFORCE

$$r = r_s(x, y)$$

is the total reward of  
the complete output

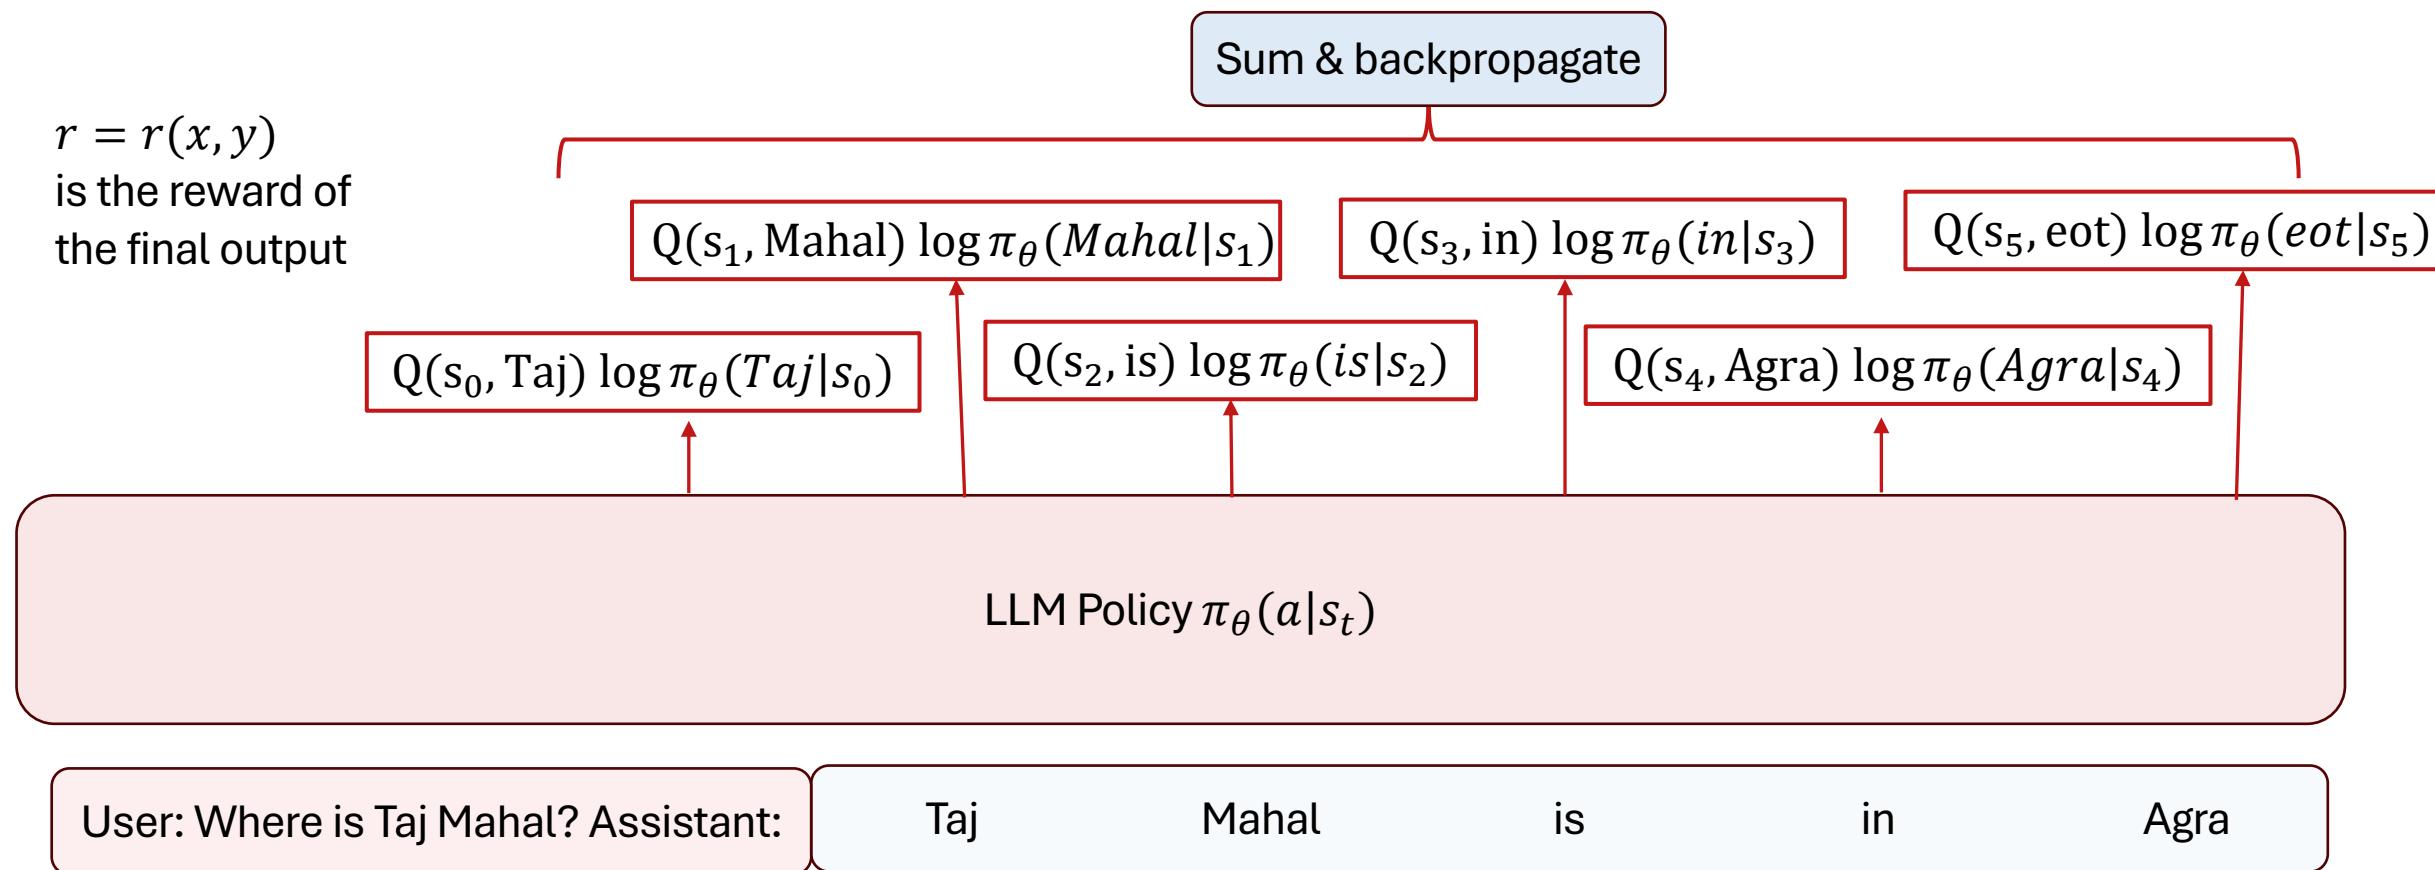

# Problems with REINFORCE

- The reward at token “Taj” depends on the tokens generated in the future
- If the model had generated “Taj Mahal is in Paris”
  - The reward would be negative
  - The probability of generating Taj would be decreased
- If the model had generated “Taj Mahal is in Agra”
  - The reward would be positive
  - The probability of generating Taj would be increased
- This variance in the reward leads to unstable training.
- To reduce variance – take the average reward over all likely sequences (under the policy) that generate “Taj” for the first token.
- This is called the  $Q$  – function

# REINFORCE with Q functions

Doesn't matter what gets generated in the future. The “reward” at token “Taj” is fixed.

# Q-function & Value function

- The Q-function for a state-action pair is the average discounted cumulative reward received at the state after taking the specified action.
- The discount factor  $\lambda$  ensures that immediate rewards get higher weight.
- The Value function of a state is the average discounted cumulative reward received after reaching the state.

# From Q-function to Advantage function

- For text generation using language models

$$s_{t+1} = (s_t, a_t)$$

- That is, once you have generated the next token, the next state is determined completely.
- Hence, the Q-function for a state-action pair can be written as

$$Q(s_t, a_t) = r(s_t, a_t) + \gamma V(s_{t+1})$$

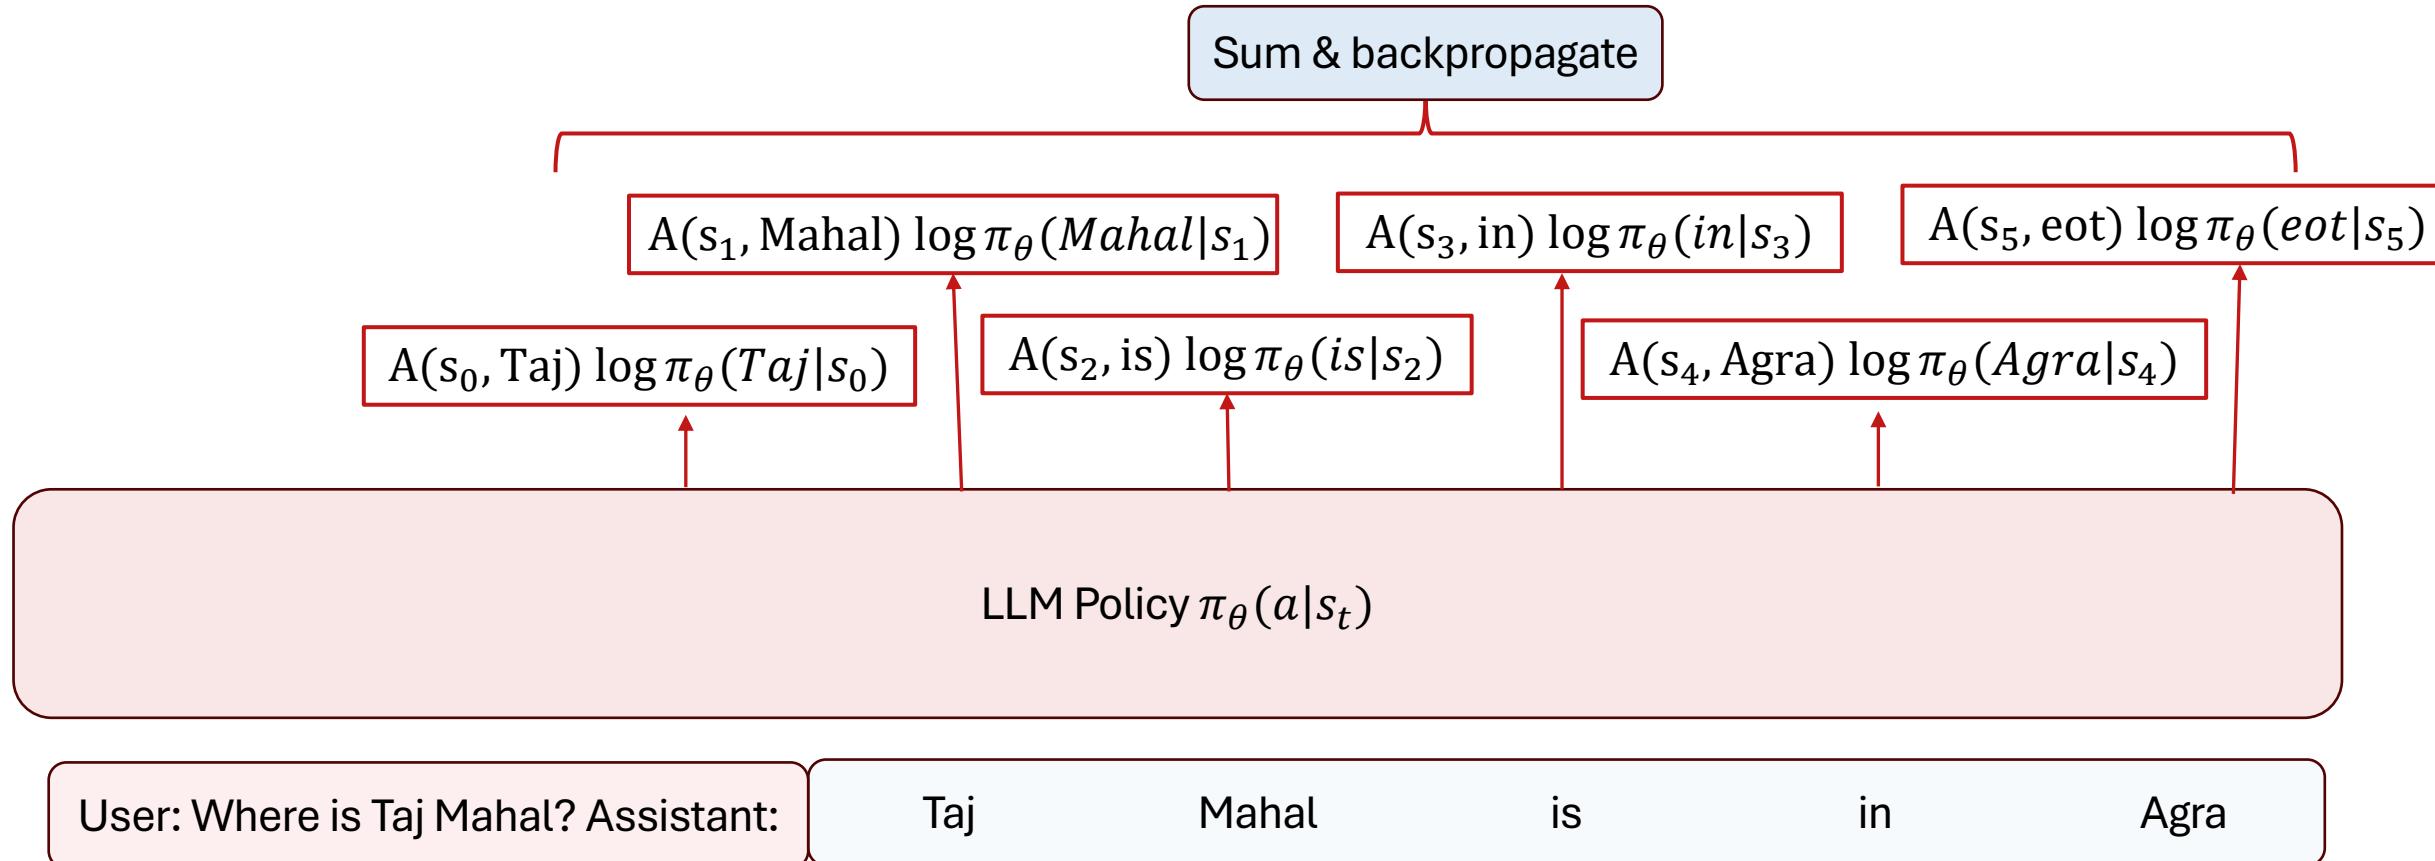

- To further reduce variance, the advantage function  $A(s_t, a_t)$  is used instead of Q-function

$$\begin{aligned} A(s_t, a_t) &= Q(s_t, a_t) - V(s_t) \\ &= r(s_t, a_t) + \gamma V(s_{t+1}) - V(s_t) \end{aligned}$$

- Intuitively, advantage function captures contribution of the action over an average action at the same state.

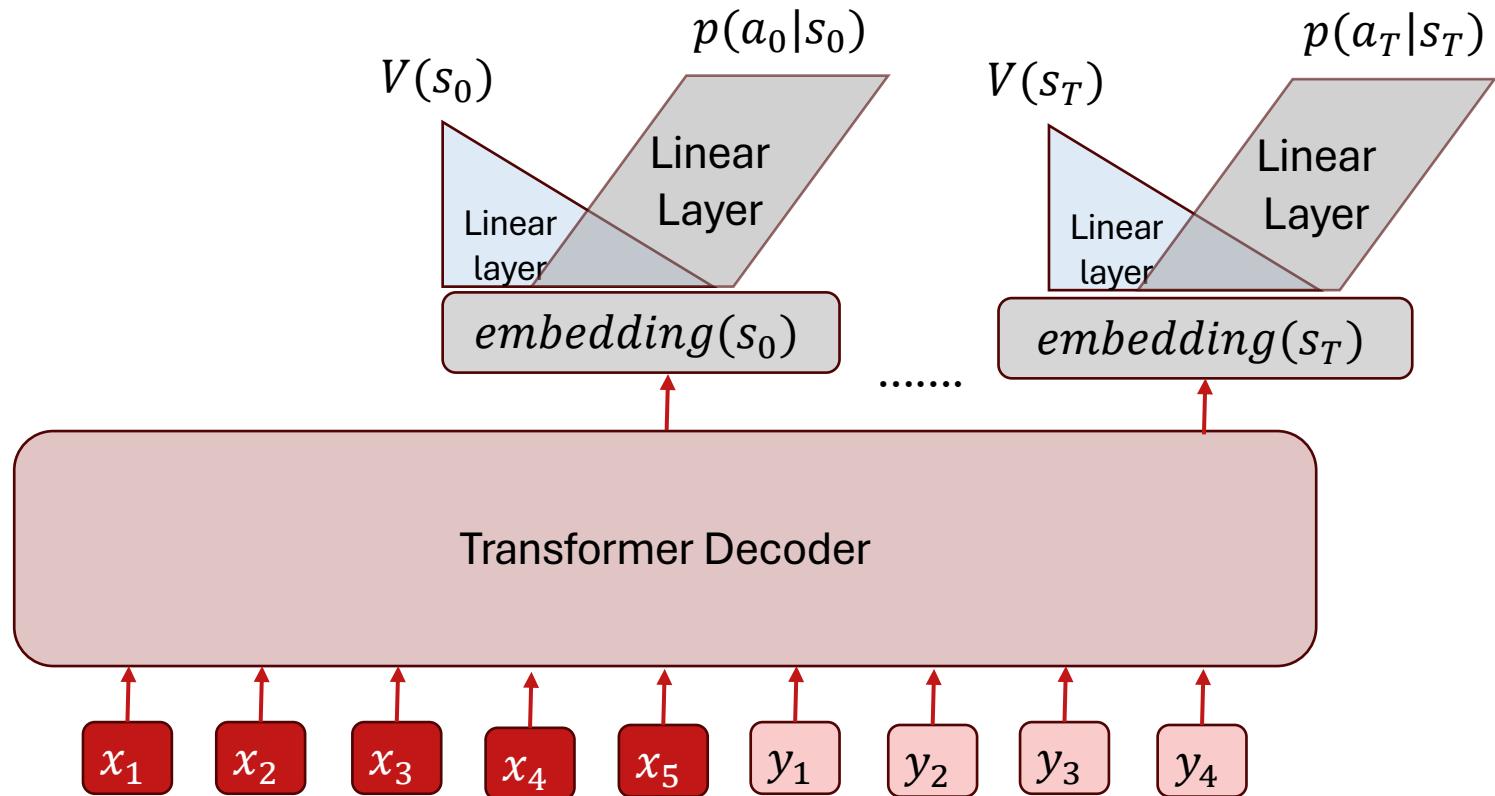

# REINFORCE with advantage functions

Doesn't matter what gets generated in the future. The “reward” at token “Taj” is fixed.

# Implementing the Value function

# Learning the Value function

- Given an input  $x$ , sample  $y = (a_0, \dots, a_T)$  from the policy  $\pi_\theta(y|x)$
- Compute the cumulative discounted reward for each time-step

$$R_t =$$

- Minimize the mean-squared error

# Vanilla Policy Gradient

- Repeat until convergence
  - Sample a batch of prompts  $B$
  - For each prompt, sample one-or more outputs
  - For each output  $y = (a_1, \dots, a_T)$ 
    - Compute the reward  $r_t$  at each token  $a_t$
    - Compute cumulative discounted reward  $R_t$  for each token
    - Compute the value & advantage function  $A_t$  for each token
  - Apply few gradient updates using REINFORCE with the advantage values computed above
  - Apply few gradient updates to train the value function by minimizing the MSE.

# Problems

- Sampling from the policy after every update can be challenging.
- Solution: Sample from an older fixed policy instead

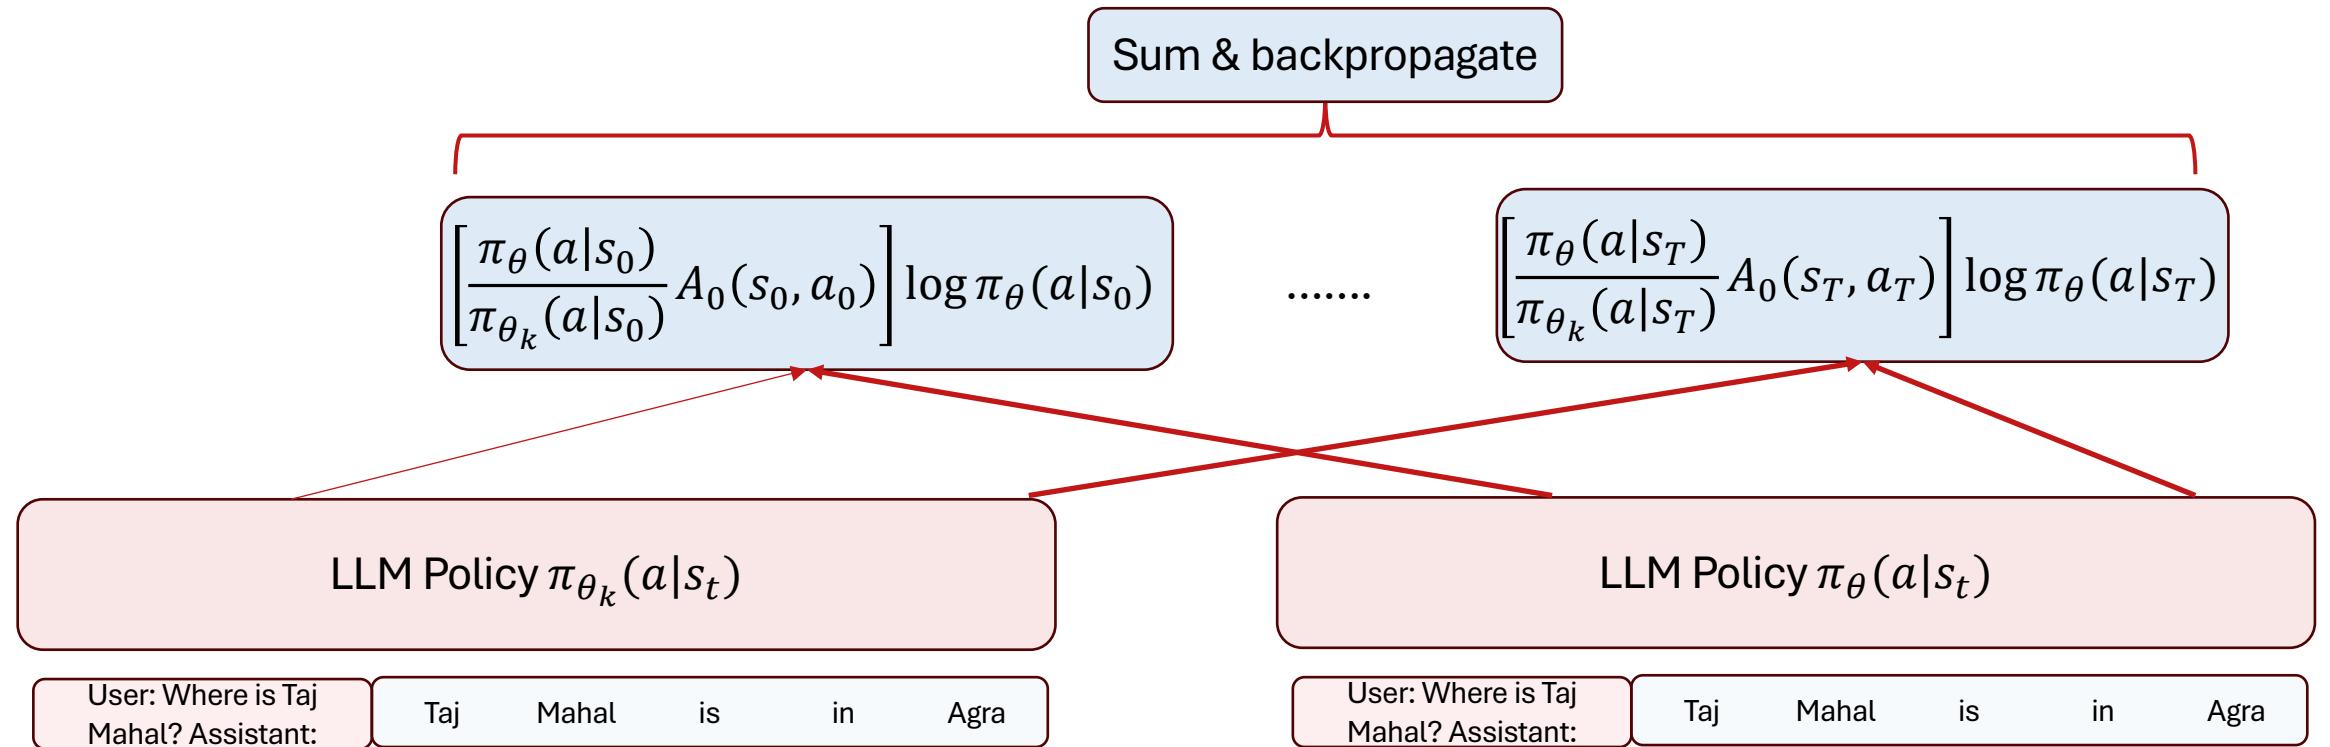

# REINFORCE with importance weights

# REINFORCE with importance weights

The term in the square brackets is kept constant during backpropagation. In Pytorch, this means using `.detach()` function

# Proximal Policy Optimization

- Keeping the batch of prompts & outputs fixed, how much can we update the policy?
- If we update too much, the importance weights can change drastically.
- PPO-CLIP

$$(1 - \epsilon) \leq \frac{\pi_\theta(a_t|s_t)}{\pi_k(a_t|s_t)} \leq (1 + \epsilon)$$

- This ensures that no matter how many updates are done to  $\pi_\theta$ , it stays close to  $\pi_{\theta_t}$

# PPO-CLIP

$$(1 - \epsilon) \leq \frac{\pi_\theta(a_t|s_t)}{\pi_{\theta_t}(a_t|s_t)} \leq (1 + \epsilon)$$

To achieve above, maximize the following

- When advantage is positive

$$\max_{\theta} \min \left( \frac{\pi_\theta(a_t|s_t)}{\pi_{\theta_k}(a_t|s_t)}, (1 + \epsilon) \right) A_t(s_t, a_t)$$

- When advantage is negative

$$\max_{\theta} \max \left( \frac{\pi_\theta(a_t|s_t)}{\pi_{\theta_k}(a_t|s_t)}, (1 - \epsilon) \right) A_t(s_t, a_t)$$

Credit: <https://spinningup.openai.com/en/latest/algorithms/ppo.html>

# PPO-CLIP with +ve advantage

$$\max_{\theta} \min \left( \frac{\pi_{\theta}(a_t|s_t)}{\pi_{\theta_t}(a_t|s_t)}, (1 + \epsilon) \right) A_t(s_t, a_t)$$

# PPO-CLIP with -ve advantage

$$\max_{\theta} \max \left( \frac{\pi_{\theta}(a_t | s_t)}{\pi_{\theta_t}(a_t | s_t)}, (1 - \epsilon) \right) A_t(s_t, a_t)$$

# The PPO-CLIP algorithm

- For  $k = 1$  to  $K$ 
  - Sample a batch of prompts  $B$
  - For each prompt, sample one-or more outputs from  $\pi_{\theta_k}(y|x)$
  - For each output  $y = (a_1, \dots, a_T)$ 
    - Compute the reward  $r_t$  at each token  $a_t$
    - Compute cumulative discounted reward  $R_t$  for each token
    - Compute the value & advantage function  $A_t$  for each token
  - Apply few gradient updates using REINFORCE PPO-CLIP with the advantage values computed above
  - Apply few gradient updates to train the value function by minimizing the MSE.

# Things to remember

- The log-derivative trick should be used to compute gradient in REINFORCE
- The log-probability of the tokens should be weighed by the advantage function to reduce variance
- Importance weights should be used to allow sampling from a fixed policy
- The importance weights should be clipped to prevent large gradient updates.
